McIDAS-V Tutorial
Advanced Scripting: User Defined Functions
updated November 2015 (software version 1.5)

McIDAS-V is a free, open source, visualization and data analysis software package that is the next generation in SSEC's 40-year history of sophisticated McIDAS software packages. McIDAS-V displays weather satellite (including hyperspectral) and other geophysical data in 2- and 3-dimensions. McIDAS-V can also analyze and manipulate the data with its powerful mathematical functions. McIDAS-V is built on SSEC's VisAD and Unidata's IDV libraries. The functionality of SSEC's HYDRA software package is also being integrated into McIDAS-V for viewing and analyzing hyperspectral satellite data.

McIDAS-V version 1.2 included the first release of fully supported scripting tools. Running scripts with McIDAS-V allows the user to automatically process data and generate displays for web pages and other environments. The McIDAS-V scripting API is written in java implementation of python called Jython. The McIDAS-V scripting library system library is still under development and new tools will be added with future releases of McIDAS-V. You will be notified at the start-up of McIDAS-V when new versions are available on the McIDAS-V webpage - http://www.ssec.wisc.edu/mcidas/software/v/.

If you encounter any errors or would like to request an enhancement, please post questions to the McIDAS-V Support Forums - http://www.ssec.wisc.edu/mcidas/forums/. The forums also provide the opportunity to share information with other users.

This tutorial assumes that you have McIDAS-V installed on your machine, and that you know how to start McIDAS-V. If you cannot start McIDAS-V on your machine, you should follow the instructions in the document entitled McIDAS-V Tutorial – Installation and Introduction. More training materials are available on the McIDAS-V webpage and in the “Getting Started” chapter of the McIDAS-V User's Guide, which is available from the Help menu within McIDAS-V.

Terminology

There are two windows displayed when McIDAS-V first starts, the McIDAS-V Main Display (hereafter Main Display) and the McIDAS-V Data Explorer (hereafter Data Explorer).

The Data Explorer contains three tabs that appear in bold italics throughout this document: Data Sources, Field Selector, and Layer Controls. Data is selected in the Data Sources tab, loaded into the Field Selector, displayed in the Main Display, and output is formatted in the Layer Controls.

Menu trees will be listed as a series (e.g., Edit -> Remove -> All Layers and Data Sources). Mouse clicks will be listed as combinations (e.g., Shift+Left Click+Drag).
Preparing for this Tutorial

Beginning users of McIDAS-V should review the material covered in the *An Introduction to Jython Scripting* tutorial before proceeding with this lesson for instruction on using the **Jython Shell**, basic Jython terminology and the preparatory material for this lesson.

This lesson will use the term “VisAD data object.” A VisAD data object contains the data as well as detailed information about a data’s structure and type. These objects can also contain units, temporal and geospatial information. In this tutorial, an introduction to the VisAD data object is presented as well as a general introduction to accessing the information within the data object.

A new scripting tool targeted for release in McIDAS-V 1.6 is being introduced in this tutorial. The beta version of the **describe()** function is included in this tutorial. Please use the **describe()** function with this knowledge and provide feedback on the [Scripting Forum](#). User input on the forums which includes bug reports, requests for new functionality, and examples of the software in use are beneficial for McIDAS-V development.

To use the **describe()** function in McIDAS-V 1.5, a plugin will need to be installed:

- a. In the **Main Display**, select **Tools -> Plugins -> Manage** to open the **Plugin Manager**.
- b. In the **Plugin Manager**, select **File -> Install Plugin From File**.
- c. Select ‘*<local-path>/Data/UserFunctions/describe_plugin.jar’*.
- d. Click **Open**.
- e. Exit McIDAS-V.
- f. Open a new session of McIDAS-V, which will automatically install the plugin.

Introduction to Data Manipulation in McIDAS-V

1. Load the ‘*<local-path>/Data/UserFunctions/load_grid.py’* script provided with this tutorial into the Jython Shell (**Tools -> Formulas -> Jython Shell**). In the **input field** of the Jython Shell, type:

   ```python
   editFile('<local-path>/Data/UserFunctions/load_grid.py')
   ```

   Click **Evaluate** (or **Shift+Enter**) to load the script into the Jython Shell. Click **Evaluate** again to execute the script.

2. Use the standard Jython function **type()** to display the class of the data contained in **h8b1**:

   ```python
   print type(h8b1)
   ```

   Click **Evaluate**.

   The **h8b1** object belongs to a class called “*MappedGeoGridFlatField.*” This class is returned when data is loaded via the **loadFile()** function.
3. The Jython built-in **type** function does not describe how the data is structured. The JPythonMethod library built into McIDAS-V contains a function called “**whatTypes()**”. This function describes the structure of any VisAD data object. **whatTypes** can be used for debugging. In the input field of the Jython Shell, type:

   ```
   print whatTypes(h8b1)
   Click Evaluate.
   ```

   The `h8b1` object domain contains latitude and longitude coordinates. The latitude and longitude coordinate unit is “degrees”. The range of the `h8b1` data object contains the data. In this case, the data are values of albedo. Albedo has no unit (Unit: 1).

4. View the data mapping. Type: **print getType(h8b1)**

   The result, `((Longitude, Latitude) -> albedo[unit:1])`, displays a map of the albedo data (stored in the range) to the latitude (stored in domain[0]) and longitude coordinates (stored in domain[1]).

5. Determine the size of the data and range of the coordinates. In the Jython Shell, type:

   ```
   h8ds = getDomainSet(h8b1); print h8ds
   Click Evaluate.
   ```

   The semicolon ( ; ) links the commands together. In this way, multiple commands can be entered on one line, and executed in sequence. This output can be interpreted with the help of other commands run earlier. For example, step 3 evaluated the **whatTypes()** function which showed that the domain index for the longitude coordinate is 0 and the latitude coordinate is 1. This can also be inferred from the **getType()** command evaluated in step 4. Therefore, in the output of **getDomainSet()**, Dimension 0 is longitude which has a range of 103.49804 to 107.775055, and Dimension 1 is latitude which has a range of 50.773067 to 53.01361. The **getDomainSet()** output also shows that the length, or number of data points in this data are 441. If a user should use `len(h8b1)`, the length of the MappedGeoGridFlatField metadata is returned.

6. Once the data object domain set of a data object is retrieved (remember, this is the set of latitude and longitude coordinates), the latitude and longitude values for each grid point can be accessed. Using the variable `h8ds` created in the previous step, type:

   ```
   h8latlons = getLatLons(h8ds)
   h8lats = h8latlons[0]
   h8lons = h8latlons[1]
   ```

   Note: The JPythonMethod **getLatLons** resets the order of the longitude and latitude coordinates. This means that the latitude values are always returned in the zero index, and the longitudes are always returned as the first index. To get return the shape of the `h8latlons` array, run:

**Conclusion:**

By following these steps, users can effectively use Jython to manipulate and understand the structure of data objects in McIDAS-V. This knowledge is crucial for advanced scripting and data analysis tasks.
import Numeric
print Numeric.shape(h8latlons)

7. Print the first four latitude points. Note: In the Jython Shell, it is a good practice to limit the size of data printed. Type, \texttt{print h8lats[0:4]}

8. Additional methods for working with this data can be found in JPythonMethods (http://www.ssec.wisc.edu/visad-docs/javadoc/visad/python/JPythonMethods.html). For example, a method to return the min/max of the data is \texttt{getMinMax()}. In the Jython Shell, type:

\texttt{print getMinMax(h8b1)}

This method returns that the range of albedo values in \texttt{h8b1} goes from a minimum value of ~0.17 to a maximum value of ~0.665.

9. An additional JPythonMethod, \texttt{getValues()}, can be used to return the data points as float values. The values returned can be saved to a variable named \texttt{myData}. In the Jython Shell, type:

\texttt{myData = getValues(h8b1)}

a. Determine the type of \texttt{myData}. In the Jython Shell, type:

\texttt{print type(myData)}

The type returned is an array.

b. What is the length of the \texttt{myData} array? Does it match the length found in the domain set? In the Jython Shell, type:

\texttt{print len(myData)}

The length is 1. This does not match the length found in the domain set. See step 9c.

c. What is the length of \texttt{myData[0]}? In the Jython Shell, type:

\texttt{print len(myData[0])}

The length is 441, which should match the length reported in \texttt{getDomainSet(h8b1)} in step 5. The actual shape of this array is a 1x441. Therefore, the first \texttt{len()} in step 9b returns the length of the first dimension of the array \texttt{myData}. In this case, since there is only one timestamp in the file, that length is 1. This is similar to a Fortran array of REAL \texttt{myData(1,441)}. An alternative way of returning the shape
of the array would be to run: `print Numeric.shape(myData)`

**Exercise 1:** Practice using the functions and methods introduced earlier in this tutorial. Use `'<local-path>/Data/UserFunctions/load_rgb.py'` for this exercise.

a. Load `'<local-path>/Data/UserFunctions/load_rgb.py'` script into the Jython Shell and evaluate the script. This script loads three bands of Himawari-8 data (three independent MappedGeoGridFlatField objects). These three bands of data are combined with the RGB function `mycombineRGB`. This will produce a data object named `rgbData`.

b. Using `rgbData`, repeat the steps above to determine the class of `rgbData` and `rgbData` structure. Note the differences between the class and structure of `h8b1` and `rgbData`.

c. What differences are there in the mapping of `h8b1` and `rgbData`?

d. How do these differences translate into the length of the unindexed array returned from `getValues(rgbData)`? Why is the length different than the dimensions of the flat field containing one band of data?

Note, the solution to Exercise 1 can be found below.

**Exercise 1 Solution:** Practice using the functions and methods introduced earlier in this tutorial. Use `'<local-path>/Data/UserFunctions/load_rgb.py'` for this exercise.

a. Load `'<local-path>/Data/UserFunctions/load_rgb.py'` script into the Jython Shell and evaluate the script. This script loads three bands of Himawari-8 data (three independent MappedGeoGridFlatField objects). These three bands of data are combined with the RGB function `mycombineRGB`. This will produce a data object named `rgbData`.

b. Using `rgbData`, repeat the steps above to determine the class of `rgbData` and `rgbData` structure. Note the differences between the class and structure of `h8b1` and `rgbData`.

```python
print type(rgbData)
This is a visad.FlatField

print whatTypes(rgbData)
The significant difference in this step is the result in the range. As opposed to the single banded data, this RGB has three components in the range. These components are the red, green and blue values of the RGB data object.

print getType(rgbData)
```

Note, the solution to Exercise 1 can be found below.
The data mapping reinforces the information from the `whatType` result.

c. What differences are there in the mapping of `h8b1` and `rgbData`?

```python
print getType(h8b1)
The data mapping reinforces the information from the `whatType` result. The data object of `h8b1` has one 1 component in the range, this is an array of albedo values:
((Longitude, Latitude) -> albedo[unit:1])
```

while the data object of `rgbData` has 3 components in the range, the red, green and blue image values:

```python
((Longitude, Latitude) -> (redimage1, greenimage1, blueimage1))
```

d. How do these differences translate into the length of the unindexed array returned from `getValues(rgbData)`? Why is the length different than the dimensions of the flat field containing one band of data?

```python
print len(myData)
The length is 1.
myRGBdata = getValues(rgbData)
print len(myRGBdata)
The length is 3.
```

### Creating Functions for the Jython Library

In this section, a function called `probe` will be created, which can be expanded to load multiple channels from the Himawari-8 satellite. Later, these data will be used in a cloud algorithm. The goal of this section is to provide the user with the knowledge base that will enable them to create their own functions to meet their research needs.

10. Using the Jython Library, create a new function called `probe()`.

   a. In the Main Display, select Tools -> Formulas -> Jython Library to open the Jython Library.

   b. In the left panel of the Jython Library, select Local Jython -> User’s Library.

   c. The right panel of the Jython Library is the location where new functions are defined.
d. **Create a new function** in the *Training Library*. Expand *Local Jython* and select *Training Library* (this library was created in the *An Introduction to Jython Scripting* tutorial). **Left-Click** in the right panel of the Jython Library. **Type**: `def probe():`

This defines a new function called `probe()`. This function will require three input parameters: the data object (2D lat/lon flat field of data), the latitude location, and the longitude location. Modify the definition line to include the input parameters. The final structure of the definition line should be: `def probe(field, lat, lon):

This function returns the data value at the input latitude and longitude location.

Next, add the return statement: `return valueAtLocation`

In Jython, a code block is defined by consistent indentation. In this example, code block indentation will be four spaces. The two lines of the code block should now be:

```
def probe(field, lat, lon):
    return valueAtLocation
```

e. **Two McIDAS-V libraries are needed for this function.** Add import statements to the code block between the definition line and the return line:

```
def probe(field, lat, lon):
    from ucar.unidata.data.grid import GridUtil
    from visad.georef import EarthLocationTuple

    return valueAtLocation
```

f. Add code to retrieve data value at input lat/lon point:

```
altitude = 0.0
loc = EarthLocationTuple(lat, lon, altitude)
valueAtLocation = GridUtil.sampleToReal(field, loc, None)
```

The completed `probe()` function is:

```
def probe(field, lat, lon):
    from ucar.unidata.data.grid import GridUtil
```
from visad.georef import EarthLocationTuple

altitude = 0.0
loc = EarthLocationTuple(lat, lon, altitude)
valueAtLocation = GridUtil.sampleToReal(field, loc, None)

return valueAtLocation

g. Select **Save** and close the **Jython Library**.

### Preparing to Test the `probe()` Function by Blending Interactive and Scripting Methods

11. The Jython method, os.path.join is used in the following sequence, if the Jython “os” module has not already been imported, import it now. In *input field* of the **Jython Shell**, type: **import os**

12. If the tutorial *An Introduction to Jython Scripting* was completed before beginning this tutorial, proceed to step 14.

13. If the step to create a local ADDE entry for the Joplin IR data was not completed in the *An Introduction to Jython Scripting* tutorial, create a local ADDE entry for data for the Joplin Tornado GOES-13 IR data. In the **Jython Shell**, type:

   ```python
   homePath = expandpath('~')
dataPath = os.path.join(homePath,"Data")

   areaPath = os.path.join(dataPath,"Scripting","tornado-areas")
irPath = os.path.join(areaPath,"IR")

   irDataSet = makeLocalADDEEntry(dataset='TORNADO', imageType='GOES-13 IR', mask=irPath, format='McIDAS Area', save=True)
   ```

14. Load this data into the **Field Selector** via the interactive **Data Chooser**. Display the data using the McIDAS-V scripting API.

   a. Bring the **Main Display** forward. In the **Jython Shell**, type:

      ```python
      activeDisplay().ToFront()
      ```

   b. Click the button on the **Main Toolbar** to bring the **Data Explorer** to the front.
c. In the **Data Explorer**, open the **Data Sources** tab.

d. Using the **Satellite -> Imagery** chooser, load the `<LOCAL-DATA>` created in previous step (**Dataset: TORNADO, Image Type: GOES-13 IR**) via the interactive Data Chooser. In the **Relative** tab, select the **5 most recent** times and click **Add Source**. Additional instructions for loading satellite imagery can be found under **Choosing Satellite Imagery** in the User’s Guide or the **Satellite Imagery Tutorial**.

e. When the Joplin data is in the **Field Selector**, click the **Jython Shell** (or select **Tools -> Formulas -> Jython Shell**) to bring the **Jython Shell** forward.

f. The Joplin data will be selected from the **Jython Shell**, and used to test the **probe()** function. In the **input field** of the **Jython Shell** type:

   ```python
   joplin = selectData('ir')
   ```

g. Click **Evaluate**. Note: The **Field** Selector title is “ir.” The title matches the string entered in the **selectData()** call.

h. In the secondary **Field Selector** window, select the **GOES-13 IR -> 10.7 um IR Surface/Cloud-top Temp -> Temperature** data source.

i. Once the bottom **Times** tab in the window becomes visible, click **OK**.

j. Display the Joplin image, type:

   ```python
   panel = buildWindow()
   panel[0].createLayer('Grid Table', joplin[0])
   ```

15. Notice the section of data displayed in the grid table with no latitude or longitude and a value of 0 for **Band4_TEMP_0**. These are points in the area that are not navigated on the earth.

   a. At the top of the **Layer Controls** turn on the option for **Show native coordinates**. Now, instead of seeing invalid latitude and longitude values, image element and image lines are listed. This demonstrates that while there are data points without a latitude and longitude, they are points included in the AREA itself.

   b. Once done interrogating the chart, turn **Show native coordinates** off.

16. For analysis and sometimes display purposes, these points can be set to "Missing". In the **Jython Shell** type:

   ```python
   joplinMiss = setMissingNoNavigation(joplin[0])
   panel[0].createLayer('Grid Table', joplinMiss)
   ```

   Notice the values are now ![Diamond] or ![Question Mark] (dependent on your platform), corresponding to a missing value.
Exercise 2: Test the `probe()` function:

a. Select five navigated points from the Grid Table display. Write the five test points in the table below:

<table>
<thead>
<tr>
<th>Latitude</th>
<th>Longitude</th>
<th>Data Value</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

b. Test the `probe` function on the five points by using each lat/lon value pair in the function call. In the **Jython Shell**, type:

```
print probe(joplinMiss, <latitude>, <longitude>)
```

c. Determine the class of `joplin` and `joplin[0]` using `print type()`. In the **Jython Shell**, type:

```
print type(joplin)
paint type(joplin[0])
```

<table>
<thead>
<tr>
<th>Data Object</th>
<th>Belongs to class</th>
</tr>
</thead>
<tbody>
<tr>
<td>joplin</td>
<td></td>
</tr>
<tr>
<td>joplin[0]</td>
<td></td>
</tr>
</tbody>
</table>

d. Using the `getType` method (`object.getType()`, inspect the data mapping of `joplin` and `joplin[0]`. Write the mapping in the space below. In the **Jython Shell**, type:
print getType(joplin)
print getType(joplin[0])

e. Use the `getImageTimes()` method on `joplin`. In the Jython Shell, type:

```
print joplin.getImageTimes()
```

Note, the solution to Exercise 2 can be found on page 12

Extra: Using the `describe()` function scheduled for release with McIDAS-V 1.6, type:

```
print describe(joplin[0])
```

Click **Evaluate**.

This function is meant to show quick statistics for a flatField or multiple flat fields. If you have questions, comments, requests for additional functionality or bug reports, please post them to the [Scripting Forum](https://example.com).

It is possible to calculate statistics on any array, provided it is converted to a VisAD field:
```
myField = field([1, 2, 3, 4, 5, 9, 9, 9, 9])
print describe(myField)
```

Click **Evaluate**.
Exercise 2 Solution: Test the `probe()` function:

a. Select five navigated points from the **Grid Table** display. Write the five test points in the table below:

<table>
<thead>
<tr>
<th>Latitude</th>
<th>Longitude</th>
<th>Data Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>53.2</td>
<td>-65.912</td>
<td>276.3</td>
</tr>
</tbody>
</table>

This chart contains one sample latitude/longitude/data point to demonstrate an example solution.

b. Test the `probe` function on the five points by using each lat/lon value pair in the function call. In the **Jython Shell**, type:

```python
print probe(joplinMiss, 53.2, -65.912)
```

This returns a value of 276.3, matching the grid table output.

c. Determine the class of `joplin` and `joplin[0]` using `print type()`. In the **Jython Shell**, type:

```python
print type(joplin)
p
print type(joplin[0])
```

<table>
<thead>
<tr>
<th>Data Object</th>
<th>Belongs to class</th>
</tr>
</thead>
<tbody>
<tr>
<td>joplin</td>
<td>visad.meteorology.ImageSequenceImpl</td>
</tr>
<tr>
<td>joplin[0]</td>
<td>visad.meteorology.NavigatedImage</td>
</tr>
</tbody>
</table>
d. Using the **getType** method (**object.getType()**), inspect the data mapping of *joplin* and *joplin[0]*. Write the mapping in the space below. In the **Jython Shell**, type: **print getType(joplin)**

```python
(Time -> ((ImageElement, ImageLine) -> Band4_TEMP))
The *joplin* data object is an image sequence, so this command shows that the time domain (which could be multiple times) is linked to the data coordinates.

Type: **print getType(joplin[0])**

((ImageElement, ImageLine) -> Band4_TEMP)
The *joplin[0]* data object is the navigated image, this reveals that the image has element and line coordinates mapped to the data.

e. Use the **getImageTimes()** method on *joplin*. In the **Jython Shell**, type:

```python
print joplin.getImageTimes()
```
This step emphasizes the point that the image sequence data object *joplin* is an image sequence and the times can be extracted as a list.
Scripting Exercise #1: Simple Radar Rain Rate Formula

Despite the complexity of the VisAD Data Model, simple mathematical transforms on data objects are easy. Standard mathematical operators work on entire VisAD objects just like they do on individual numbers. This exercise will demonstrate use of arithmetic operators on VisAD data objects to calculate rain rate from radar reflectivity.

Many simple empirical relationships between rain rate and radar reflectivity have been derived over the years. The following table lists a few; these all take the same mathematical form.

![Table 1. Z-R RECOMMENDATIONS](http://www.ou.edu/radar/z_r_relationships.pdf)

17. Note: The rain rate formulas above are in terms of radar reflectivity Z. However, Level 3 radar products give radar reflectivity in dBZ ("decibels of Z"), so the following conversion is needed: dBZ = 10\log_{10}(Z). In addition, units of mm/hr are converted to in/hr for easy comparison to other NEXRAD products later on.

   a. Type the following Jython function into your Jython Library (or paste from file marshall_palmer.py).

   ```python
   def marshall_palmer(dbz):
       a = 200.0
       b = 1.6
       z = 10.0**(dbz/10.0)
       r_mmhr = (z/a)**(1/b)  # rainrate [mm/hr]
       r_inhr = r_mmhr/25.4    # rainrate [in/hr]
       return newUnit(r_inhr, 'in/hr', 'in/hr')
   ```
b. Create a formula using this Jython function.
   1. Select Tools -> Formulas -> Create Formula from the Main Display.
   2. For Description and Name, type: marshall_palmer
   3. For Formula, type: marshall_palmer(dbz)
   4. Click Add Formula.

c. Create a data source for the five most recent times of Base Reflectivity 123nm (NOR) data for a station with active ongoing precipitation (check an online radar mosaic to find a good station!). Display the data.
   2. For Collection, select Nexrad Level III Radar from IDD.
   3. For Product, select Base Reflectivity 124nm (NOR).
   4. In the Station panel, select a station with active precipitation.
   5. In the Times panel, select 5 most recent.
   6. Click Add Source.
   7. In the Field Selector, select the BaseReflectivity -> BaseReflectivity Elevation Angle .5 field and the Radar Sweep View in 2D display type. Click Create Display.

d. In the Field Selector, click the Formulas data source, and select your marshall_palmer formula. Select the Radar Displays -> Radar Sweep View in 2D display type and click Create Display. In the Field Selector window, select the Level III Radar Data -> BaseReflectivity -> BaseReflectivity Elevation Angle .5 field for the dbz field and click OK.

e. You should now have your Marshall-Palmer rain rate displayed. Choose an enhancement table and range to make precipitation features stand out. Probe the reflectivity and rain rate values. Do the Marshall-Palmer rain rates seem realistic?

f. Go back to the Radar -> Level II -> Remote chooser, and use the procedure from step 17c to display Digital Instantaneous Precipitation Rate (DPR) for the same station. Does it compare well to Marshall-Palmer?

g. Optional exercise: starting with the marshall_palmer Jython function above, implement one function for each rain rate formula in the table above. Use what you have learned about Python syntax to avoid repeat code. When finished, determine if any of these formulas match the DPR product better than Marshall-Palmer. An example solution is available at <local path>/Data/UserFunctions/rainrate_solution.py.
Scripting Exercise #2: Build a Himawari-8 Cloud Mask (Comprehensive Exercise)

Using loadGrid, the Jython Library, and knowledge of the VisAD data object, build a simple cloud mask algorithm for Himawari-8’s new AHI sensor. This exercise will extend your knowledge of the VisAD data model by using methods to extract raw data arrays from VisAD data objects and operate on the data arrays in a way that is familiar to users already comfortable with programming languages like MATLAB® or Fortran.

First, explore a Himawari-8 scene interactively and determine cloud/no-cloud thresholds for various AHI channels. Next, add the outline of a Jython cloud mask function provided to your Jython Library. Implement the algorithm of the cloud mask Jython function with the thresholds determined interactively. Finally, run the algorithm as many times as needed while exploring the results. Iterate between interactively assessing thresholds and algorithm development until you are satisfied with the cloud mask.

18. Load Himawari-8 bands interactively and determine cloud thresholds. The Himawari-8 data distributed with this tutorial is split into a single band per file. For example, band 3 contains the string “B03” at the end of the filename. Create a data source per band you are interested in.

   a. Add a data source for band 1.
      1. In the Data Explorer, open the Data Sources tab and navigate to the Gridded Data -> Local chooser.
      2. Under Data Type, select “Grid files (netCDF/GRIB/OPeNDAP/GEMPAK)”.
      3. Navigate to ‘<local path>/Data/H8’ and Double-Click the file HS_H08_20150415_0420_B01_FLDK.subset.nc.

   b. Repeat step 18a for other bands of interest. Add a data source for at least three more bands, including band 3 (high resolution visible channel), band 9 (a channel with high water vapor absorption), and band 14 (an infrared window channel).

   c. Display the data for band 1.
      1. Create a new one panel map tab in the Main Display window.
      2. In the Data Sources panel of the Field Selector, select the top HS_H08* data source. The order of the data sources in this panel is determined by the order they were added. Since band 1 was added first in step 18a, this is at the top of the list.
      3. Open the Data Sampling tab. Uncheck Use Default, and set X and Y to “All Points”.
      4. Choose the Plan Views -> Color-Shaded Plan View display type and click Create Display.

   d. Create a Data Probe/Time Series display for all data sources created in steps 18a and 18b.
      1. In the Data Sources panel of the Field Selector, select the top HS_H08* (band 1) data source. Choose the Data Probe/Time Series display type.
      2. Click Create Display.
3. To avoid confusion as more layers are added to the display, change the parameter name below the chart from albedo to Band 1. To do this, Right-Click on albedo below the chart and choose Parameter albedo -> Chart Properties. In the Properties window, set the Legend Label field to be Band 1 and click OK. An alternative way of getting to the Properties window for a layer in the chart is to Double-Click on the parameter.

   e. Add the other fields added in step 18b to the Data Probe/Time Series display. In the Layer Controls of the Data Probe/Time Series display, Left-Click on the Band 1 data readout line to select the line.

      1. Once the line is highlighted, Right-Click to select Add Parameter....
      2. Use the secondary Field Selector select the other fields, clicking Add Selected>> after each addition.
      3. When all the desired fields have been added to the panel below Add Selected>> click OK.
      4. Repeat the last step in 18d to set the parameter name of each field to be the band number.

   f. Explore the scene. Using the Data Probe (hold down the middle mouse button over the display) and the Data Probe/Time Series display, write down a cutoff value that is representative of the transition from not cloudy to cloudy. This is just to get started – clearly, you won’t find a single value for a single channel that works perfectly for the entire scene.

19. Copy the script ‘<local-path>/Data/UserFunctions/ahi_cloudmask.py’ to the Jython Library. This is the outline of a cloud mask script that can be improved in later steps. Try running the cloud mask provided without modification:

   a. Open ahi_cloudmask.py in a text editor.

   c. Create a new Jython Library by selecting File->New Jython Library from the menu. Enter AHI-cloudmask and click OK.

   d. Open the Local Jython -> AHI-cloudmask library. Copy and paste the text in ahi_cloudmask.py from the text editor into the library and click Save.

   e. Open the Jython Shell (click Tools -> Formulas -> Jython Shell) and type:

   run_ahi_cloudmask()
   Click Evaluate.
   You should get a new display showing a cloud mask, but at this point it is pretty bad! It misses most of the clouds in the scene.
20. Modify the cloud mask function to implement the thresholds you determined in step 18:

a. In the Jython Library, examine the `ahi_cloudmask()` code pasted in the previous step. The code locates the AHI data on the disk, loads it into McIDAS-V with `loadGrid`, and then organizes it by band number in a Python dictionary for easy access. For the purposes of this exercise, the focus will be on the function `do_cloudmask` (ahi_cloudmask.py line 7), which implements the cloud mask algorithm. The outline of this function is already implemented; it is up to the user to fill in the cloud/no-cloud thresholds determined in step 18.

b. Now, implement your cloud mask. The portion of the script you will work on is labeled “You can fill in additional clear/cloudy tests here”. Directly above this comment, there are two tests already implemented, one for band 14 and another for band 1. These tests use the function `mask` from `JPythonMethods` to create a simple cloud/no-cloud mask based on brightness temperature or reflectance threshold. Modify these two tests with the thresholds determined for band 1 and band 14 in previous steps. For example, assuming you wrote down a threshold of 260K for band 14, change the line:

   ```
   threshold_mask = mask(ahi_datas[14], 'gt', 220.0, False)
   ```

to

   ```
   threshold_mask = mask(ahi_datas[14], 'gt', 260.0, False)
   ```

c. Now, copy the block labeled “Test number 2” (line 43), and paste it directly below. Change the comment to “Test number 3”, change the dictionary key to the next channel you would like to work on, and change the threshold as desired.

d. Redo the previous step to implement all the thresholds you determined.

e. Once all of the cloud mask tests have been added to the library, click Save at the bottom of the Jython Library.

f. In the Jython Shell, rerun `run_ahi_cloudmask()` and examine the results. Has your cloud mask improved?

g. These brightness temperature and reflectance threshold tests are simple to define and run quickly because they can be implemented with built-in functions like `mask` that operate on an entire VisAD data object in a single function call. You may ask: what if I have an algorithm that cannot be expressed using functions from `JPythonMethods`? For example, cloudy areas are often more spatially heterogeneous than cloud-free areas and decide you want to develop a test that considers the standard deviation of neighboring pixels as a simple measure of spatial heterogeneity.

   To illustrate this, the file ahi_cloudmask.py has already implemented a function called `do_std_dev_test`, but it is initially unused by `do_cloudmask`. As the first step, modify `do_cloudmask` to use `do_std_dev_test`. This part is simple because `do_std_dev_test` returns a VisAD Data object (similar to what is returned by `mask`) that can be multiplied by the current cloud mask result to obtain the combined cloud mask:

   ```
   return threshold_mask
   ```
becomes

```python
std_dev_mask = do_std_dev_test(ahi_datas)
return threshold_mask*std_dev_mask
```

h. In the Jython Shell, rerun `run_ahi_cloudmask()` and examine the results. Inspect both large, spatially uniform clouds, and smaller spatially complex clouds. How did the standard deviation test affect the results? What are the test’s strengths and weaknesses? To see the results of `do_cloudmask` clearly, modify `do_cloudmask` so that it only uses the `do_std_dev_test` mask.

i. The algorithm used by `do_std_dev_test` is simple: calculate the standard deviation of a 3x3 array of pixels surrounding a given pixel for some channel, and label that pixel cloud or clear based on some threshold for that channel. However, this cannot be expressed with `JPythonMethods`! So, the implementation must loop through each pixel, extract the neighboring pixels, and calculate the standard deviation of that set of pixels. This has a performance cost (Jython is an interpreted language, not a compiled one, so long `for` loops will be slow) but it is the only way to implement this algorithm in pure Jython. Here is a more detailed description of the implementation of `do_std_dev_test`:

1. Create an array to write to contain the cloud mask result. The easiest way to do that is to clone() one of the input data objects:

   ```python
   output = ahi_datas[14].clone()
   ```

2. The full VisAD data object is not needed, we just want the data array it is holding on to. This is done with `getFloats(False)[0]`. In this case, `False` means the values of the array are not copied, however, the range of the array is maintained (If `getFloats(True)` is used, the cloud mask modifications will not affect the output!). The index, `[0]`, in the `getFloats(False[0])` statement indicates that the first “range component” of the object is selected. This pattern will work for most VisAD data objects. A common exception is a VisAD data object that represents an RGB image; in that case, there are three “range components”, so `[0]` refers to the red image, `[1]` refers to the green image, and `[2]` refers to the blue image. Back to the present case, the full line of code to get the data array is:

   ```python
   outFloats = output.getFloats(False)[0]
   ```

The array is named `outFloats` to signify it is an array of floating point values. This combination of `clone` and `getFloats` is a common pattern in McIDAS-V Jython for obtaining an output array to write a result to.

3. The next section is similar to the previous step, but a new Python dictionary called `ahi` is defined and used. Each key in `ahi` is mapping to a data array for that band. This a convenient reference to the data array for each band later on:

   ```python
   ahi = dict()
   for data_key in ahi_datas.keys():
       ahi[data_key] = (ahi_datas[data_key].getFloats(False))[0]
   ```

4. Next, iterate through each pixel. We use the Python function `enumerate` to get a reference to both the index `i` and the value of
the image at \( i \) (hereafter, the value of the image at the index \( i \) will be called \textbf{pixel}): 

\begin{verbatim}
for i, pixel in enumerate(outFloats):
\end{verbatim}

5. Next, the standard deviation tests are done. For each pixel, extract the surrounding 3x3 pixels using a helper function called \texttt{get\_3x3}. VisAD internally represents all data as a 1-dimensional array, so the dimensionality must be handled correctly. The key to the implementation is determining how many elements are in each scan “line” using the function \texttt{getDomainSizes}. Use that scan line element size information to skip ahead to the same horizontal location in the next “line”. Inspect the implementation of \texttt{get\_3x3} and convince yourself that it is correct.

6. Finally, implement one more helper function called \texttt{std\_dev} that calculates the standard deviation of a list of numbers according to the usual statistical formula. Send the result of \texttt{get\_3x3} into \texttt{std\_dev} to obtain a simple measure of spatial heterogeneity, and experimentally determine useful thresholds to label the current pixel cloudy or clear.

21. Modify your thresholds for brightness temperatures, reflectances, and standard deviations as needed until you are happy with the cloud mask. Feel free to implement other tests you may think of, such as channel differences.
